CUMULATIVE EMISSIONS, UNBURNABLE FOSSIL FUEL AND THE OPTIMAL CARBON TAX

Armon Rezai, Vienna University of Economics and Business^{*}

Frederick van der Ploeg, University of Oxford^{§ ‡}

Abstract

A new IAM is used to calculate the optimal tradeoff between, on the one hand, locking up fossil fuel and curbing global warming, and, on the other hand, sacrificing consumption now and in the near future. This IAM uses the Oxford carbon cycle, which differs from DICE, FUND and PAGE in that cumulative emissions are the key driving force of changes in temperature. We highlight how time impatience, intergenerational inequality aversion and expected trend growth affect the time paths of the optimal global carbon tax and the optimal amount of fossil fuel reserves to leave untapped. We also compare these with the adverse and deleterious global warming trajectories that occur if no policy actions are taken.

Keywords: unburnable fossil fuel, cumulative emissions, optimal carbon tax, Oxford carbon cycle, trend growth, intergenerational inequality aversion, time impatience

1. Introduction

Climate scientists have warned that to have a 50-50 chance of limiting global warming to not more than 2 degrees Celsius above the average global temperature of pre-industrial times throughout the twenty-first century cumulative carbon emissions between 2011 and 2050 need to be limited to 1,100 gigatonnes of carbon dioxide (Gt CO₂) or 300 gigatonnes of carbon (GtC) (Allen et al., 2009 Meinshausen et al., 2009; Clarke et al., 2014).¹ Recent calculations suggest that this necessitates that one third of oil reserves, half of gas reserves and over four fifths of coal reserves must remain untapped from 2010 to 2050 (McGlade and Ekins, 2015). This study uses an ad-hoc combination of the top-down model MAGICC to give a probability distribution of the temperature rise trajectories for a given carbon emissions profile taking macroeconomic trends as given and the bottom-up model TIAM-UCL to calculate how much of each fossil fuel can be burned in each region.

The integrated assessment model (IAM) most often used by economists and policy makers is DICE (Nordhaus, 2014).² This general equilibrium IAM has the advantage that it can explain macroeconomic trends and changes in the carbon cycle in a coherent and consistent manner. However, it supposes that all fossil fuel is abundant and thus cannot speak to the key question of how much fossil fuel to abandon in order to limit global warming.

Most IAMs that are used in the policy debate such as PAGE (Tol, 2002ab), FUND (Hope, 2006) or DICE are quite complex and difficult to comprehend for the outsider (if accessible to the public at all). Furthermore, although figures for the optimal carbon tax derived from these IAMs deliver headline-grabbing numbers, it is less clear to the uninitiated where these numbers precisely come from and how reliable the underlying global damages used in these IAMs are from a scientific point of view (Pindyck, 2013). The only IAM that does give estimates of the amount of fossil fuel to be locked up (McGlade and Ekins, 2015) does not perform an optimal tradeoff between locking up fossil fuel and the resulting curbing of global warming, on the one hand, and consumption sacrifices that have to be made to achieve this today and in the near future, on the other hand.

¹ According to the IPCC (2014), cumulative emissions have to be limited to an uncertainty range of 700-860 GtC if global warming is to remain below 2°C. With 520 GtC emitted by 2011, this gives a tight carbon budget range of 180-320 GtC.

² Simulations based on DICE also supported the recommendations of the Stern Review (Stern, 2007).

Our objective is to demonstrate how the global carbon tax and the amount of unburnable fossil fuel depend on ethical parameters such as the society's rate of time impatience and intergenerational inequality aversion, the extraction cost technology, the rate of technical progress in renewable energy and the estimate of the future trend rate of economic growth. We offer back-on-the-envelope rules for the global carbon tax and how much fossil fuel to leave unburnt. We do not specify a ceiling for the carbon budget, but derive the climate policies that maximize social welfare and optimally trade off making sacrifices by current generations and those in the near future to limit global warming in the more distant future within a simple and transparent framework.

To back up our arguments, we put forward a new IAM of macroeconomic growth and climate change with three features that are not present in the DICE, FUND or PAGE models (Rezai and van der Ploeg, 2015). First, we allow extraction costs to increase as the finite stock of fossil fuel reserves is depleted. This creates a scarcity rent on fossil fuel and a motive not to burn all available reserves. Second, existing IAMs have used rather simple carbon cycles on coarse time grids with the implication that the amount that is left of burning one ton of carbon today at any future is independent of past or current stocks of carbon in the atmosphere. Others have shown that the carbon cycle of DICE can be well represented with a two- or three-box carbon cycle (Golosov et al., 2014; Gerlagh and Liski, 2013), but also abstract from history dependence. The Oxford carbon cycle (e.g., Allen et al., 2009) does give a role for memory and captures the carbon cycle and temperature changes much better and we therefore use this as our carbon cycle. For this cycle cumulative carbon emissions are the main driving force of changes in global mean temperature and this is why we focus on cumulative emissions too. Third, our IAM optimally determines the time at which fossil fuel is phased out and renewable energy is phased in. The transition to the carbon-free phase occurs at the moment that the rise in extraction costs as reserves are depleted plus the rise in the social cost of carbon together with the fall in the cost of renewable energy are sufficiently strong to price fossil fuel out of the market. Our IAM has a finer, annual grid than other IAMs so the timing of energy transitions can be pinpointed more precisely.

Other features of our IAM are more familiar. We have a Ramsey model of macroeconomic growth and convergence with capital, labor and energy fuel as factors of production, use the global warming damages of DICE, and suppose that renewable

energy is not competitive today but will become so in the future as technical progress reduces their cost while the cost of fossil fuel increases with cumulative extraction. Overall technological progress proceeds along its historic average of roughly 2% per annum and world population continues to grow to a plateau of 12 billion. We will highlight the importance of different expectations about future trend growth for climate policy in our simulations.

2. Some simple insights into optimal climate policy

A simple rule for the optimal global carbon tax τ (in dollars per ton of emitted carbon) at time t is (e.g., Golosov et al., 2014; Gerlagh and Liski, 2014; Rezai and van der Ploeg, 2014) $\tau(t) = \Omega(r)\chi Y(t)$, $\Omega'(r) < 0$, where $\chi = 0.002379$ is the damage flow as a fraction of world GDP corresponding to burning one gigatonne of carbon, Y is world GDP, and r is the growth-corrected rate used to discount global warming damages. With global warming damages proportional to world GDP (roughly as in DICE), the optimal global carbon tax is proportional to world GDP too. The function $\Omega(r)$ corresponds to the present discounted values of what is left at each point of time in the future of burning one ton of carbon today, suitably corrected for the lag between changes in the stock of atmospheric carbon and global mean temperature. This captures the DICE carbon cycle fairly well, but for the Oxford carbon cycle the history of emissions matters and thus the optimal global carbon tax should be written as

$$(1) \quad \tau(t) = \Omega(r, H(t))\chi Y(t), \quad \Omega'(r) < 0,$$

where $H(t)$ denotes the history of fossil fuel emissions at time t . The insight that the optimal global carbon tax is proportional to world GDP and decreases with the growth-corrected interest rate is thus unaffected. In economic growth models, the standard Keynes-Ramsey rule gives the growth-corrected social rate of interest

$$(2) \quad r = RTI + (IIA - 1)g,$$

where $RTI > 0$ is the rate of time impatience, $IIA \geq 0$ the coefficient of relative intergenerational inequality aversion and g is the rate of trend growth. If there is little concern for the welfare of future generations (high RTI), the interest rate will be high and the global carbon tax low as future damages are discounted more heavily. Provided

$IHA > 1$, growth implies that future generations are richer and thus that current generations are less prepared to make sacrifices to curb global warming in the distant future especially if intergenerational inequality aversion is strong. Higher growth then leads to a higher social rate of interest and to a lower carbon tax.

The cost of extracting fossil fuel increases as fewer reserves are left, so that the easiest accessible resources are explored first. Extraction cost at time t is thus $C(S(t))$, $C' < 0$, where $S(t)$ denotes reserves at time t . The optimal amount of fossil fuel to be locked up at the end of the fossil fuel phase follows from the condition that the marginal cost of fossil fuel extraction plus the carbon tax must equal the cost of renewable energy, since at the time of the energy transition, say T , the scarcity rent of fossil fuel vanishes. Hence, $C(S(T)) + \xi\tau(T) = b(T)$, $T > 0$, where $\xi > 0$ denotes the carbon emission per unity of energy (the emission intensity) and $b(t)$ the unit cost of infinitely elastically supplied renewable energy at time t . Using the functional specification $C(S(t)) = \gamma_0 (S(0)/S(t))^{\gamma_1}$ together with (1) and (2), we derive the amount of unburnt fossil fuel as a function of fundamental ethical, technological and geophysical parameters:

$$(3) \quad \frac{S(T)}{S(0)} = \left(\frac{\gamma_0}{b(T) - \xi\tau(T)} \right)^{\frac{1}{\gamma_1}} = \left(\frac{\gamma_0}{b(T) - \xi\Omega(RTP + (IHA - 1)g, H(T))\chi Y(T)} \right)^{\frac{1}{\gamma_1}}.$$

Since unburnt fossil fuel increases in the global carbon tax, a lower rate of time preference or less intergenerational inequality aversion lowers the rate used to discount damages and pushes up the carbon tax and thus leaves more of each fossil fuel unburnt. A higher damage coefficient or a higher level of world GDP at the time of the switch to the carbon-free era also pushes up the carbon tax, so more of each fossil fuel is left in the ground. Also, more of a fossil fuel is left unburnt if the cost of extracting (γ_0) are high and the cost of its carbon-free alternative ($b(T)$) is low. Further, more fossil fuel is left unburnt if the emissions intensity (ξ) is large.³ To the extent that solar energy is a cheap substitute for coal in, say, electricity generation, more of coal reserves must be

³ For example, the tar sands are expensive and have a high emissions intensity so it is best to keep as much (if not all) of these reserves unexploited. Conventional natural gas and shale gas are relatively cheap to extract and have lower emissions intensity than oil, coal or tar sands. This suggests that much less of gas reserves should be abandoned. Coal is very cheap to extract and has relatively high emissions intensity, so much of coal reserves will be used unless carbon is properly priced.

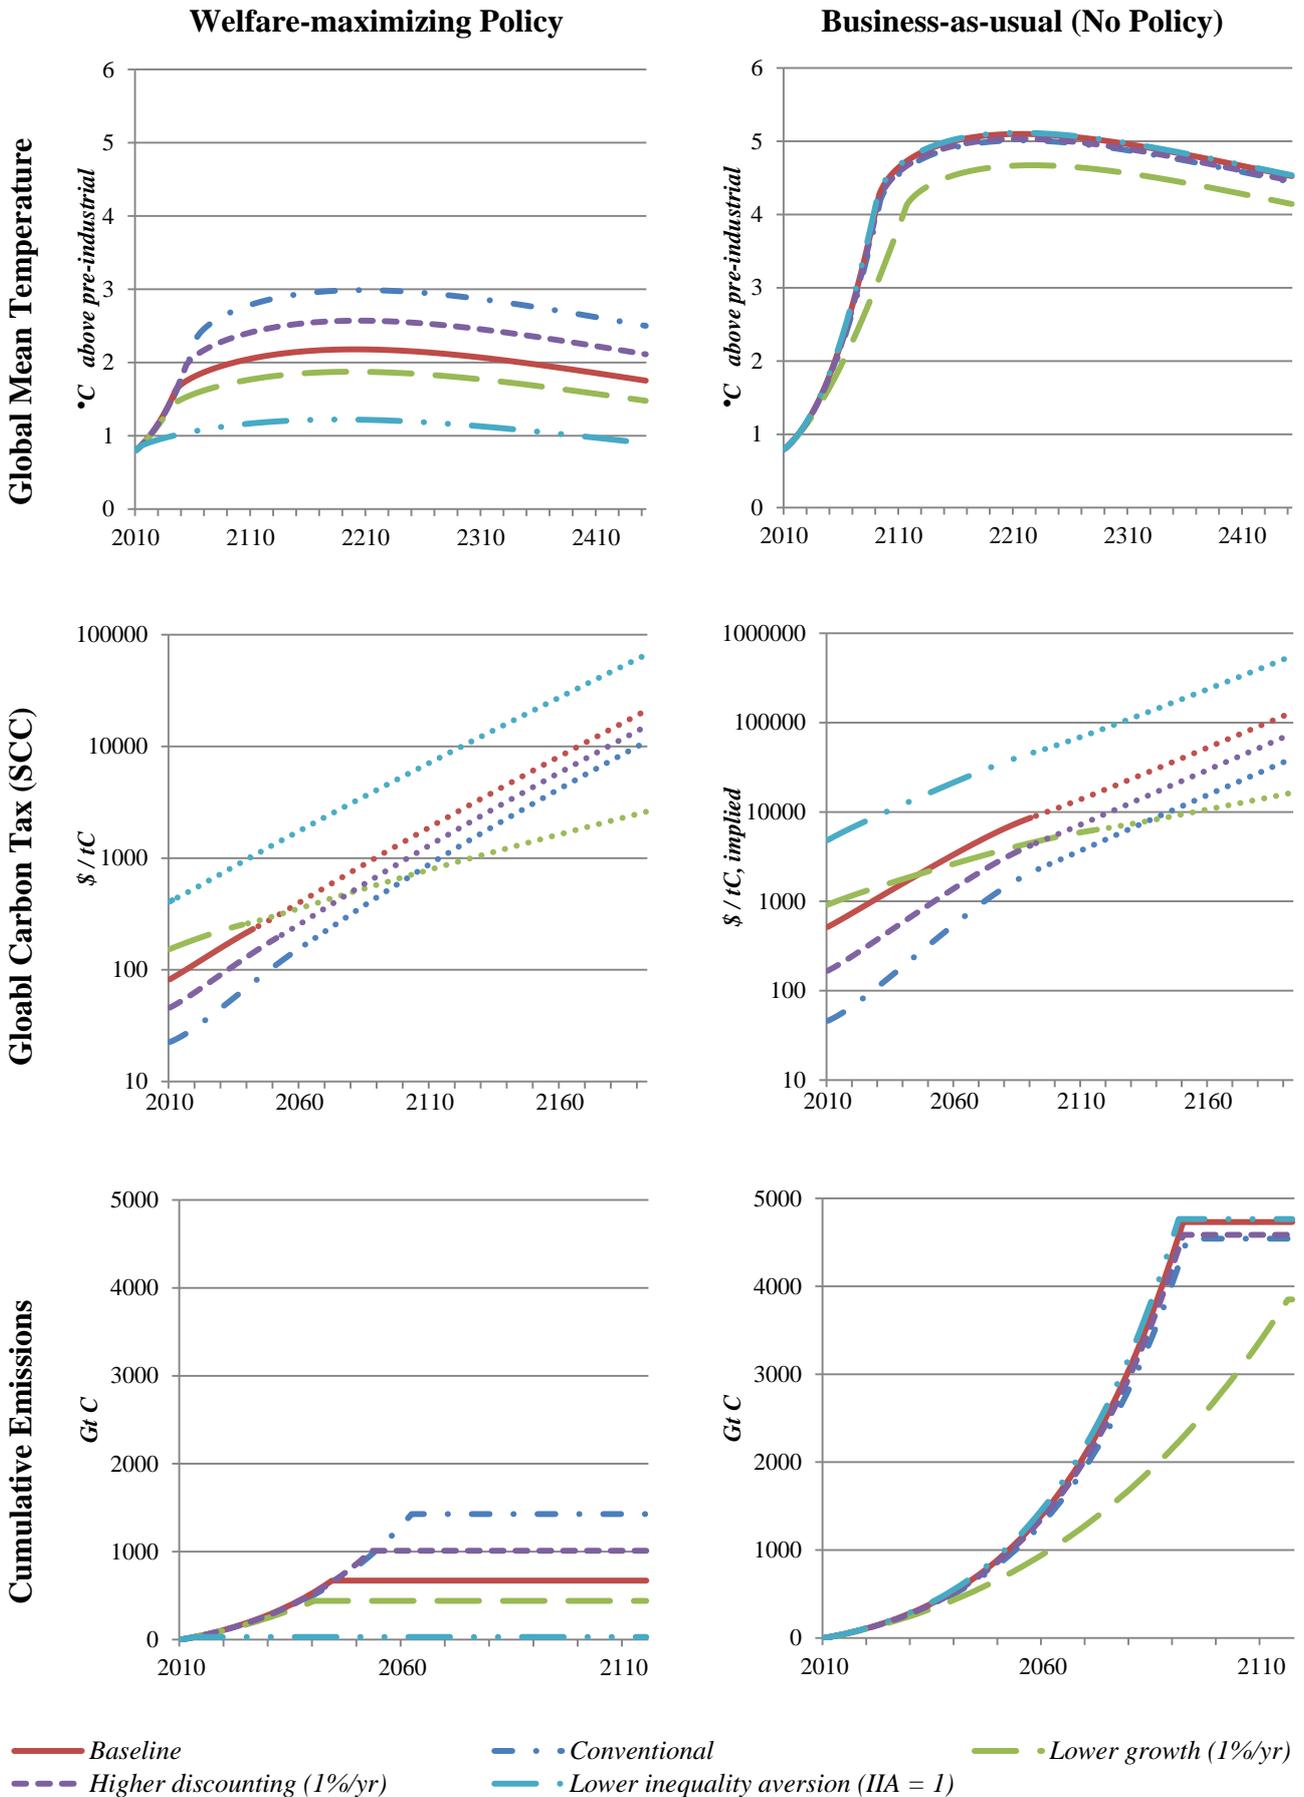

left unused. The stock of untapped fossil fuel indicates how much fossil fuel is burned which translates into cumulative carbon emissions. It thus follows that cumulative emissions and global warming are curbed if the rate of time impatience (*RTI*), intergenerational inequality aversion (*IIA*) and (if $IIA > 1$) trend growth are lower, extracting fossil fuel is more expensive and renewable energy is cheaper. Finally, if σ units of fossil fuel are needed per unit of output, the optimal time of the energy transition is approximately

$$(4) \quad T = \frac{1}{g} \ln \left(1 + g \frac{S_0 - S(T)}{\sigma Y(0)} \right), \quad g \neq 0, \quad T = \frac{S_0 - S(T)}{\sigma Y(0)}, \quad g = 0.$$

Equation (4) shows that fossil fuel is abandoned more quickly if the economy and the associated demand for fossil fuel ($\sigma Y(0)$) are large, the total amount of burnt fossil fuel ($S_0 - S(T)$) is small, and the rate of economic growth (g) is high. Using (3), we see that a higher weight to the welfare of future generations (lower *RTI*) and less intergenerational inequality aversion (lower in *IIA*) lowers the amount of burnt fossil fuel and thus speeds up the transition to the carbon-free economy.

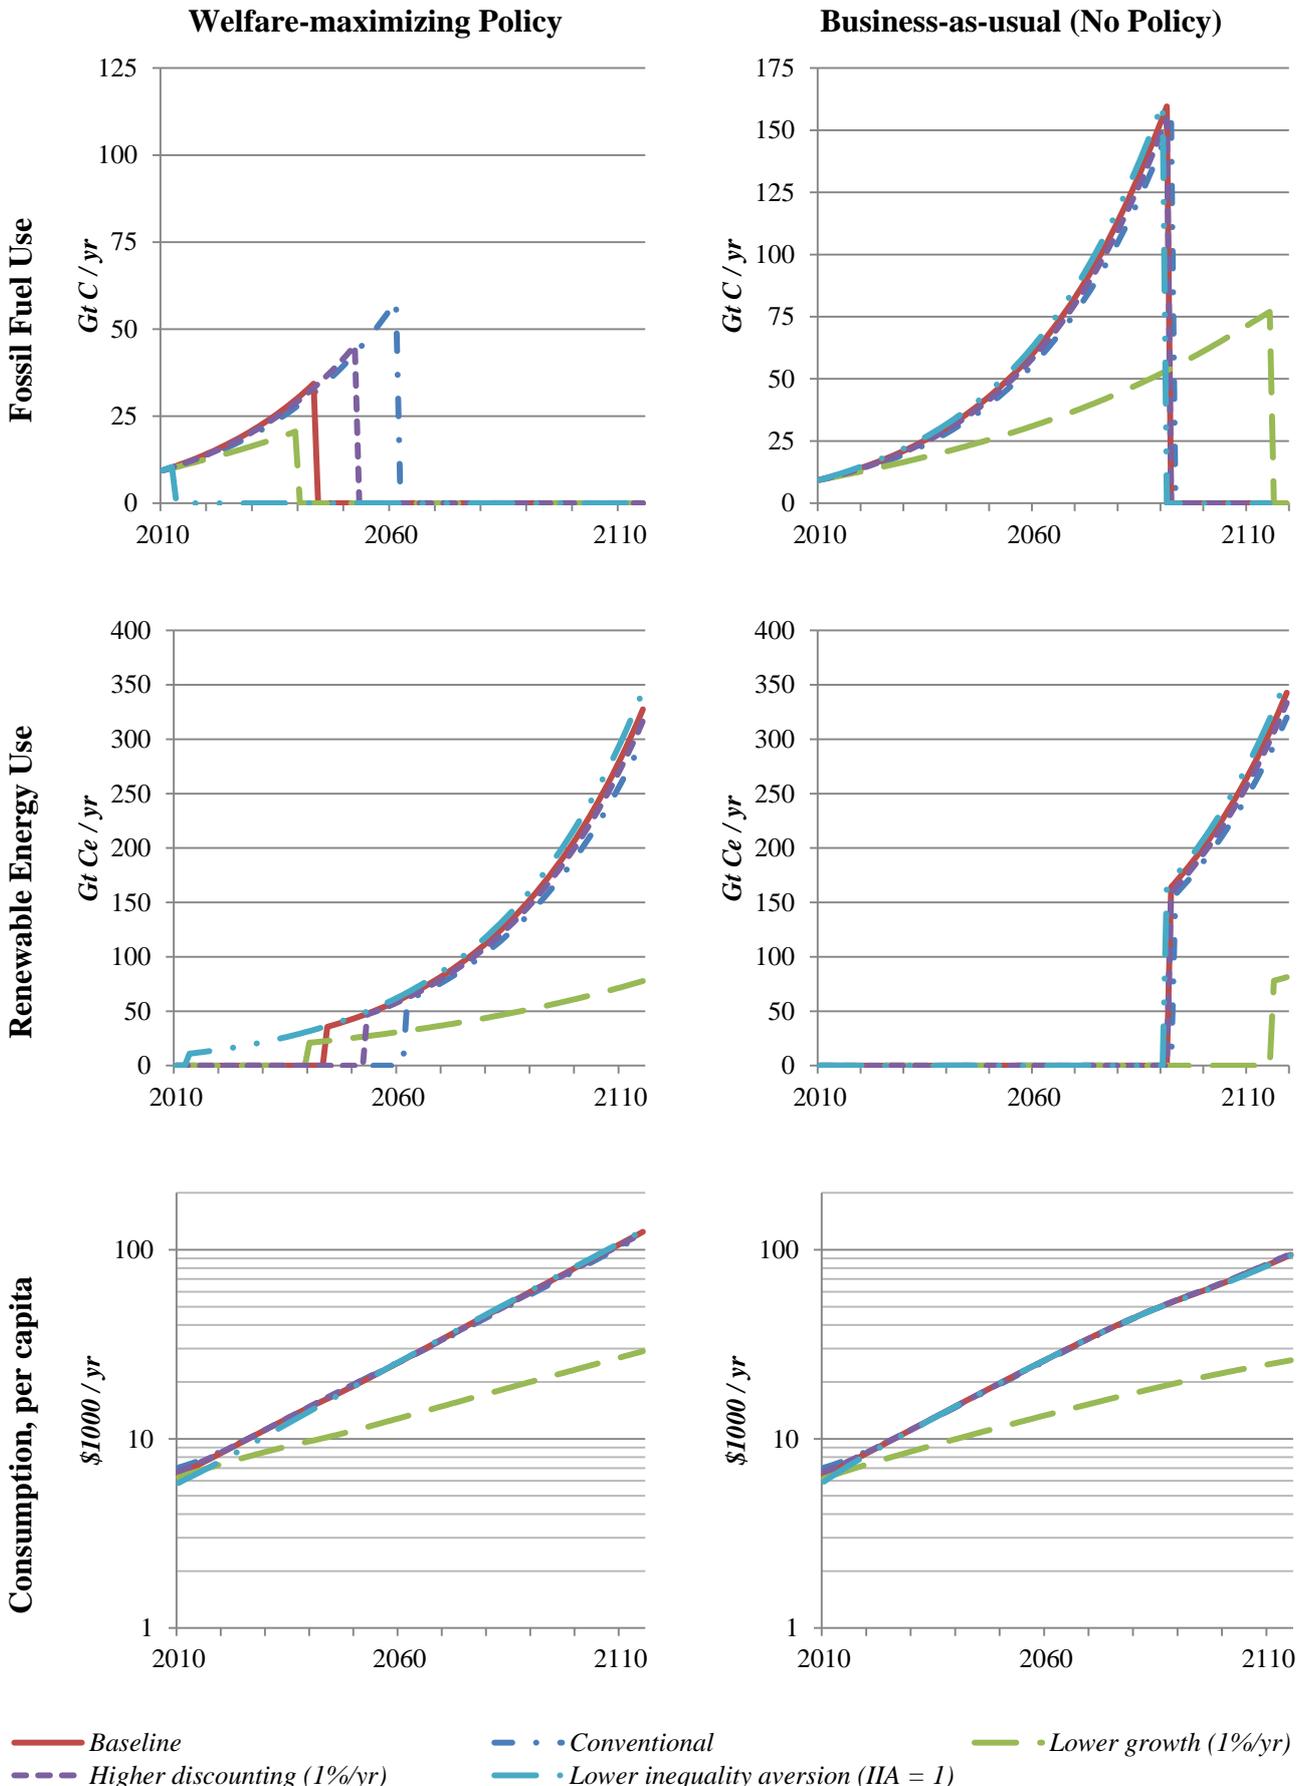

3. Policy simulations

To demonstrate the robustness of the insights obtained from (1)-(4), we present simulations for the optimal carbon tax and the business-as-usual (BAU) outcomes from our general equilibrium IAM with stock-dependent extraction costs, optimal energy transitions and Oxford carbon dynamics. In the baseline simulations we assume that the *RTI* is 0.1% per annum (Stern, 2007), *IIA* is 1.45 (Nordhaus, 2014) and productivity growth is 2% per annum (Barro, 2014). Table 1 presents these numbers and also a set of four sensitivity runs in which we analyse the effect of changes in the key parameters appearing in (1)-(4). We also present a ‘conventional’ scenario which meets the standard assumptions economists make about the social rate of time impatience, the degree of intergenerational inequality aversion, and the trend growth rate of productivity. Figure 1 reports the equilibrium trajectories for select key variables for the welfare-maximizing case (left panel) and BAU where no policy action is taken, i.e., the carbon tax remains at zero (right panel).

Key Baseline (RTI = 0.1%, IIA = 1, $g = 2\%$) yields rapid decarbonization mid-century, limiting global warming to slightly above 2°C. Conventional economic parameters (RTI = 1%, IIA = 2, $g = 2\%$) delay the transition by one decade and lead to temperature increases of 3°C.

Figure 1: Sensitivity analysis for the optimal SCC and cumulative emissions

Key: Business-as-usual leads consistently to high temperature deviations of 5°C. Only lower expected growth in living standards reduces cumulative demand for fossil fuel.

Figure 1 (cont'd): Sensitivity analysis for the optimal SCC and cumulative emissions

We start with BAU (right panel) to illustrate the disastrous prospects for the world and highlight the need for climate policy. Without a carbon tax, firms are not forced to internalize the deleterious effects of fossil fuel and the market price of fossil fuel is sufficiently low for continued use of the dirty but cheaper input for most of the century. In the baseline BAU case 4,760 GtC are burnt and global temperature peaks above 5 °C. This is in sharp contrast with the social optimum where only an eighth as much carbon is burnt and temperature peaks slightly above 2°C (see discussion below). What is more, a maximal warming of 5°C and cumulative carbon emissions in excess of 4,500 GtC are a consistent feature of all our BAU simulations, regardless of the degree of RTI and IIA as these parameters mostly influence the carbon tax (which is zero in BAU). The trend growth rate does have a significant impact on BAU, but only on the timing of fossil fuel use in (4). As the economy grows more slowly, less fossil fuel is used in each period. This pushes out the time at which the economy switches to the carbon-free phase and allows technological progress in renewable energy generation to continue. Peak temperature is, however, only slightly lowered with cumulative emissions of about 4,000 GtC, which is still more than 10 times the carbon budget compatible with keeping global warming below 2 degrees Celsius. Given our simulations, BAU clearly is not an environmentally viable option. Fortunately, it is also very unattractive from a purely economic point of view not to adopt climate policy.

Optimal climate policy responds to the tradeoff between, on the one hand, locking up fossil fuel and curbing global warming, and, on the other hand, sacrificing consumption now and in the near future and, abstracting from the collective actions problems vexing current climate negotiations, suggests that welfare is maximized under a complete decarbonisation of the economy by mid century in the baseline scenario (red, solid) or by 2070 at the latest in our sensitivity runs. The left panel in figure 1 illustrates that in the base line the optimal carbon tax is set to limit global warming to 2.2°C, starting at \$82/tC and rising at about 3% per annum over the next two centuries. Stringent climate policy of this form increases the price of fossil fuels rapidly enough that fossil fuel is phased out and carbon-free alternatives are phased in mid-century. At this point, cumulative emissions amounting to 670 GtC will have been burnt and all remaining fossil fuel reserves will be abandoned. This favorable scenario contrasts starkly with the business-as-usual case discussed above.

Scenario	Color	RTI	IIA	g	r	Cumulative emissions	Maximum temperature
<i>Baseline</i>		0.1%	1.45	2%	1%	670 GtC	2.2 °C
<i>Lower IIA</i>		0.1%	1	2%	0.1%	30 GtC	1.2 °C
<i>Lower trend growth</i>		0.1%	1.45	1%	0.55%	440 GtC	1.9 °C
<i>Higher Discounting</i>		1%	1.45	2%	1.9%	1,010 GtC	2.6 °C
<i>Conventional</i>		1%	2	2%	3%	1,430 GtC	3 °C

Table 1: Policy Scenarios, equilibrium interest rates, and cumulative emissions

Given the assumptions about RTI , IIA and g , we can compute the equilibrium interest rate in (1). For the baseline scenario, r is 1% per annum. The rules in (1) and (2) allow us to predict the effects of changes in parameter values on the optimal carbon tax, cumulative emissions, and peak temperature. Increasing the RTI to 1% per annum increases the interest rate with which damages are discounted from 1% to 1.9% per annum and, consequentially, lowers the carbon tax. Fossil fuel therefore remains competitive for longer, leading to increased cumulative emissions and higher peak warming. The simulations in figure 1 confirm this prediction, with the initial tax falling to \$45/tC, cumulative emissions and maximal warming rising to 1,010 GtC and 2.6°C, respectively.

Figure 1 also reports the effect of lowering the degree of intergenerational inequality aversion to 1. This reduces the social interest rate r to 0.1% per annum, and therefore increases the carbon tax (to \$408/tC), curbs cumulative emissions (to 30 GtC) and lowers global warming (to 1.2°C). More pessimism about future growth prospects, say, lowering g to 1%, roughly halves the social interest rate which leads to a near doubling of the initial carbon tax to \$153/tC but also flattens the growth trajectory of the carbon tax (to roughly 2% per annum). The overall effect is still a reduction in cumulative emissions to 440 GtC and of peak temperature to 1.9°C.

We also report the outcomes for what we deem the ‘conventional’ parameter set in the economics profession (e.g., Weitzman, 2007). In the presence of positive productivity growth, the higher discount rate and the higher degree intergenerational aversion lead to a significantly higher interest rate of 3% per annum. The economic intuition behind this is that with a lower RTI and higher IIA , current generations are less willing to sacrifice

their own economic well-being which is at a lower level than that of future generations which are expected to be significantly wealthier due to persistent growth in productivity and living standards. The higher social interest rate lowers the carbon tax to \$22/tC as future damages are discounted more heavily. The price of fossil fuel remains below that of renewable energy for longer and cumulative emissions increase to 1,430 GtC, inducing temperature to peak at 3°C.

4. Conclusions

The failure of markets to price carbon emissions appropriately leads to excessive fuel use and global warming. Climate policy corrects this planetary market failure and imposes the social cost of deleterious carbon emissions on the users of fossil fuel by levying a global carbon tax (or setting up a market for tradable emission permits), thereby limiting cumulative carbon emissions. Most of climate economics tries to calculate the social cost of carbon, or the optimal carbon tax, using large, intransparent numerical IAMs, which are unable to shed light on the optimal amount of fossil fuel to leave unburnt. We have given some simple formulae to show how the global carbon tax and the amount of untapped fossil fuel can be calculated on the back-on-the-envelope given estimates of society's rate of time impatience and intergenerational inequality aversion, the extraction cost technology, the rate of technical progress in renewable energy and the future trend rate of economic growth.

Our numerical general equilibrium IAM with stock-dependent extraction costs, endogenous energy transitions and Oxford carbon dynamics shows that with business as usual global warming leads to unacceptable degrees of peak global warming, around 5°C. This highlights the urgency and scale of the climate policy challenge. Our estimates of the optimal time paths for the carbon tax significantly curb cumulative fossil fuel use to 670 GtC. As a consequence, peak temperature reduces to 2.2°C in our baseline scenario but ranges between 1.2°C and 3°C across scenarios with cumulative emissions ranging from 30 to 1430 GtC. Climate policy is more ambitious if future generations get more weight, intergenerational inequality aversion is less, and the expected trend rate of economic growth is lower. The optimal carbon tax is proportional to world GDP so that future development in the productive capacity of the economy is a crucial driver of the optimal carbon tax.

In as far as our optimal climate policy based on the DICE estimates of global warming damages lead to more than 2°C global warming more climate adjustments need to be made. An obvious one is that a rising carbon tax will in itself increase the rate of technical progress in renewable energy production and speed up the transition away from fossil fuel. To the extent that there is learning by doing, a renewable energy subsidy is called for (Rezai and Van der Ploeg, 2014). Another one is that a rising carbon tax induces additional carbon capture and sequestration. This may well be an essential component of assuring that global warming remains below 2°C (Allen et al., 2009).

A crucial research question is how markets will respond to a 2°C world with stringent climate policy. In the absence of viable sequestration options, cumulative emissions of 300-670 GtC should be compared with existing reserves of the 7 big international oil companies. Carbon Tracker and The Guardian have highlighted the issue in a recent fossil disinvestment campaign.¹ However, any economic disconnect between the planetary carbon budget constraint and existing reserves depends on the current book value of these reserves. We believe that contemporary accounting practices are guarding against an artificial overvaluation of international oil companies and it does not seem appropriate to warn about stranded assets of oil companies. However, we leave this for future research and conclude that, notwithstanding, the planet should get used to the idea that large chunks of fossil fuel reserves should remain untapped.

Appendix

Our IAM is effectively the one presented in Rezai and van der Ploeg (2015), but with the Oxford carbon cycle instead of the carbon cycle of DICE or Golosov et al. (2014). The economic part of our IAM is calibrated to data for 2010: world GDP is 63 trillion US \$, the initial capital stock is 150 trillion US \$ and initial energy use is 9.44 GtCe. The world population is 6.5 billion in 2010 and is assumed to rise to 10 billion at the end of the century and to stabilize at 12 billion. We assume a depreciation rate for capital of 10% per annum and a Cobb-Douglas technology with 30% and 70% as the shares of capital and labor, respectively. We assume that for each trillion of output that is produced $\sigma = 0.15$ GtC of fossil fuel is needed, which is in line with a Leontief technology. The initial cost of renewable energy $b(0)$ is initially \$800/tCe. The rate of technical progress in renewable energy is initially 1% per annum and then slows down to 0.5% per annum during the first 50 years and to below 0.1% per annum in 150 years. The cost function for oil extraction has \$350/tC ($\gamma_0 = 0.35$) which gives the share of energy in output of about 5%. Extraction costs evolve with $\gamma_1 = 0.5$ and the initial stock of fossil fuel reserves is 10,000 GtC. This means that initially renewable energy is more than twice as expensive as fossil energy. Since we measure fossil fuel use in GtC, the emissions intensity is $\xi = 1$.
